A nonlinear lumped-parameter model of a piezoelectric stack actuator has been developed to describe actuator behavior for purposes of control system analysis and design, and, in particular, for microrobotic applications requiring accurate position and/or force control. In formulating this model, the authors propose a generalized Maxwell resistive capacitor as a lumped-parameter causal representation of rate-independent hysteresis. Model formulation is validated by comparing results of numerical simulations to experimental data. Validation is followed by a discussion of model implications for purposes of actuator control.

Actuation for Interactive Micromanipulation

Micromanipulator applications, and in particular dynamically interactive micromanipulation, require control actuators that can provide both accurate position tracking performance in addition to robustly stable force control [2, 7, 13]. These objectives are significantly compromised by the presence of backlash and Coulomb friction in the control plant [4, 14, 16], the effects of which are exaggerated at small scales [5]. Since piezoelectric stack actuators are monolithic and have no sliding or rolling parts, they exhibit no significant mechanical stiction or backlash. Additionally, a typical lead-zirconate-titane (PZT) piezoelectric stack actuator can perform step movements with a resolution on the order of a nanometer, has a bandwidth on the order of a kilohertz, and can provide mechanical power on the order of several watts. Consequently, piezoelectric ceramics are well suited for use as precision microactuators for micropositioning devices, and due to the absence of Coulomb friction and backlash, are especially well suited for use in dynamically interactive micromanipulation applications.

The use of PZT stack actuators for accurate and stable control of manipulator position and/or force is greatly facilitated by model-based control system analysis and design. The purpose of the model presented herein is to map the relationship between voltage and charge at the electrical port of the PZT to force and displacement at the mechanical port in a lumped parameter form that can be represented by a set of ordinary differential equations.

This type of formulation provides both general insight into PZT behavior as well as a specific causal mathematical representation for purposes of model-based control system analysis and design.

The Anatomy of a Piezoelectric Stack Actuator

Piezoelectric ceramics transduce energy between the electrical and mechanical domains. Application of an electric field across the ceramic creates a mechanical strain, and in a similar manner, application of a mechanical stress on the ceramic induces an electrical charge. The fundamental component of a piezoelectric stack actuator is a wafer of piezoelectric material sandwiched between two electrodes. Prior to fabrication, the wafer is polarized uniaxially along its thickness, and thus exhibits significant piezoelectric effect in this direction only. A typical piezoelectric stack actuator is formed by assembling several of the wafer elements in series mechanically and connecting the electrodes so that the wafers are in parallel electrically, as illustrated in Fig. 1. The nominal quasi-static behavior of a piezoelectric stack actuator is a steady-state output displacement that is monotonically related to the voltage input.

Existing Descriptions of Piezoelectric Behavior

The most widely recognized description of piezoelectric ceramic behavior was published by a standards committee of the IEEE Ultrasonics, Ferroelectrics, and Frequency Control Society, originally in 1966 and most recently revised in 1987 [15]. This committee formulated linearized constitutive relations describing piezoelectric continua which form the basis for the model of piezoelectric behavior that is presently in general use. The linearized constitutive relations are typically represented in a compressed matrix notation as follows:

\[ S_i = s^E_{ij}T_j + d_{ij}E_j \]
\[ D_k = d_{ik}T_k + e_{ik}E_k \]

where \( S \) represents the strain tensor, \( s^E \) is the elastic compliance matrix when subjected to a constant electrical field, \( T \) represents the stress tensor, \( d \) is a matrix of piezoelectric material constants, \( E \) is the electric field vector, \( D \) the electric displacement vector, and \( e \) the permittivity measured at a constant stress. The compressed notation eliminates redundant terms by representing the symmetric stress and strain tensors with single column vectors that incorporate elements representing both the diagonal and off-diagonal tensor terms. These equations essentially state that the material strain and electrical displacement (charge per unit area) exhibited by a piezoelectric ceramic are both linearly affected by the mechanical stress and electrical field to which the

Goldfarb is an assistant professor in the Department of Mechanical Engineering at Vanderbilt University, and can be reached at Box 1592 Station B, Nashville TN, 37235, or via email at goldfarb@vuse.vanderbilt.edu. Celanovic was a student in the Department of Mechanical Engineering at Vanderbilt at the time the work was performed, and is presently with the Department of Electrical Engineering at Virginia Polytechnic University. A version of this article appears in the proceedings of the 1996 IEEE International Conference on Robotics and Automation, Minneapolis, MN, April 1996.
ceramic is subjected. Aside from the awkward notation, these linearized constitutive relations fail to explicitly describe the nonlinearities that are present in all piezoelectric ceramics. Additionally, the derivation assumes a purely conservative energy field, and thus fails to describe the dissipative behavioral aspects of the ceramic.

Several authors have utilized these linearized constitutive relations to derive a piezoelectric actuator model [6, 10, 12]. Given the aforementioned limitations of the IEEE model, however, the resulting descriptions are too approximate for use in developing accurate position or force control. Leigh and Zimmerman took an iterative algorithmic approach to describing the nonlinear behavior of piezoelectric ceramics [11]. Though capable of describing the hysteretic behavior of piezoelectrics, this approach is neither real-time nor energy-based, and thus provides little physical insight into actuator behavior and has limited use with respect to model-based control system design. Jouaneh and Tian incorporated a time-dependent nonlinear state variable, a method originally developed by Bouc for a structures application, to describe the nonlinear voltage/displacement behavior of piezoelectric actuators [1, 8]. The model of Jouaneh and Tian is nicely posed, but as an electromechanical model is incomplete, since it represents both the electrical and mechanical ports of the PZT as signal ports (i.e., the model implicitly assumes no dynamic interaction with the environment). Utilizing piezoelectric ceramic as an actuator explicitly requires that it perform work on its environment. An accurate behavioral description must therefore characterize the input and output ports of the PZT as power ports, and must therefore describe relationships involving mechanical force and electrical charge as well as electrical voltage and mechanical displacement.

The model presented herein offers a complete behavioral description that is based neither on the IEEE constitutive relations, nor on algorithm, but rather is formulated by describing the observed static and dynamic behavior of a piezoelectric actuator with a lumped-parameter energy-based representation.

**Model Formulation**

Since piezoceramic is a known dielectric, one would expect a PZT stack actuator to exhibit capacitive behavior. The electrical behavior of the actuator, however, is significantly more complex. For purposes of controller design, one of the most inconvenient aspects of the actuator behavior is the rate-independent hysteresis exhibited between voltage and displacement as well as between force and displacement, as shown in Fig. 2. If not specifically addressed, this type of behavior can cause closed-loop limit cycling and possibly instability. Experimental observation indicates that the rate-independent hysteresis exhibited in Fig. 2 is not present between the endpoint displacement of the

![Voltage/Displacement Hysteresis](image1)

![Force/Displacement Hysteresis](image2)

*Fig. 2. Measured quasi-static relationships between applied voltage and endpoint displacement and between applied force and endpoint displacement.*
PZT stack actuator and the net electrical charge delivered to the actuator. Additionally, dynamic observation indicates that endpoint displacement as a function of electrical charge is well approximated by second-order linear dynamics, as shown in the measured data of Fig. 3.

The quasi-static force-displacement relationship of a PZT stack actuator is shown in Fig. 4. As illustrated in the figure, rate-independent hysteresis is observed only when the electrode leads are shorted. When the leads are open and current cannot flow through the ceramic, the actuator exhibits no static hysteresis. This evidence, along with the absence of static hysteresis between displacement and charge illustrated by Fig. 3(a), suggests that the rate-independent hysteresis lies solely in the electrical domain between the applied actuator voltage and resulting charge.
Fig. 4. Quasi-static force displacement relationship for a PZT stack actuator with open leads (dashed line) and with shorted leads (solid line).

Modeling Hysteresis

Generalized hysteretic behavior is characterized by two variables related by a non-single-valued function, as illustrated by the voltage/displacement relationship in Fig. 2. Examples of such behavior include the relationship between the stress and strain in the elastic-plastic deformation of a material, and the relationship between magnetic field strength and flux density in a hard magnetic material. In these and in most physical systems, this hysteretic behavior is the result of energy storage that is fundamentally coupled to rate-independent dissipation. Mechanically, such behavior could be modeled by the combination of an ideal spring, which represents pure energy-storage, coupled to a pure Coulomb friction element, which represents rate-independent dissipation. This analogy is the basis for describing the static hysteresis exhibited by the piezoelectric actuator. Fig. 5 illustrates a single elasto-slide element which consists of a massless linear spring and a massless block that is subjected to Coulomb friction. The constitutive behavior of this element can be described by:

$$F = \begin{cases} f(x-x_b) & \text{if } |k(x-x_b)| < f_i \\ f_i \text{sgn}(x) & \text{and } x_i = x - \frac{f_i}{k} \text{sgn}(x) \text{ else} \end{cases}$$

(3)

where $x$ is the input displacement, $F$ is the output force, $k$ is the stiffness of the spring, $f = \mu N$ is the breakaway friction force of the block, and $x_b$ is the position of the block. For a displacement input of sufficient amplitude, the relationship between the applied force and the endpoint displacement will exhibit rudimentary hysteretic behavior. If several of these elasto-slide elements are put in parallel, each subjected to an incrementally larger normal force (i.e., each has an incrementally larger breakaway force), the simple relationship of Fig. 5 becomes a piecewise linear approximation of rate-independent hysteresis, as illustrated in Fig. 6. This construction was initially formulated by the mathematician and physicist James C. Maxwell in the mid-1800s, and in the limit as the number of elasto-slide elements becomes infinite, the model is referred to as Generalized Maxwell Slip [9]. The constitutive behavior of the system in Fig. 6 containing $n$ elasto-slide elements can be described by:

$$F_i = \begin{cases} k_i(x-x_b) & \text{if } |k_i(x-x_b)| < f_i \\ f_i \text{sgn}(x) & x_i = x - \frac{f_i}{k_i} \text{sgn}(x) \text{ else} \end{cases}$$

(4)

$$F = \sum_{i=1}^{n} F_i$$

(5)

where $x$ is the input displacement, $F$ is the output force, and $F_i, k_i, f_i,$ and $x_b$ are the output force, spring stiffness, breakaway force, and block position, respectively, of the $i^{th}$ elasto-slide element.

The Maxwell model of rate-independent hysteresis can be parameterized directly from a piecewise linear fit of the rising curve of the hysteresis from a relaxed state, as illustrated in Fig. 7. Note that complete parameterization of the entire hysteretic
behavior requires fitting only the initial rising curve. A rising curve fit by \( n \) linear segments will require \( n \) elasto-slide elements, and will thus require \( 2n \) parameters. For a curve fit by \( n \) linear segments, the slope of the \( j \)th segment (the localized stiffness) is given by:

\[
s_j = \sum_{i=1}^{n} \frac{k_i}{x_i}
\]

where \( k_i \) represents the stiffness of the \( i \)th spring in the Maxwell model. This can be expressed in a matrix form as:

\[
s = A \mathbf{k}
\]

where \( s \) is a \( n \times 1 \) vector of the segment slopes, \( A \) is an \( n \times n \) upper triangular matrix of ones, and \( \mathbf{k} \) is an \( n \times 1 \) vector of Maxwell spring stiffness, as illustrated in Fig. 8. Rearranging gives an explicit expression for the spring stiffnesses:

\[
\mathbf{k} = A^+ s.
\]

The location of each respective segment, defined by \( x_j \) in the five segment fit of Fig. 7, can be expressed as:

\[
x_j = \frac{f_j}{k_j}
\]
where \( f_j \) is the breakaway friction force of the \( j \)th block in the Maxwell model. Rearranging gives an explicit expression for the breakaway forces:

\[
f = Kx
\]

(10)

where \( f \) is an \( n \times 1 \) vector of the breakaway forces, \( K \) is an \( n \times n \) diagonal matrix of the spring stiffnesses, and \( x \) is an \( n \times 1 \) vector of the segment locations as shown in Fig. 7. Note that since the Maxwell model is a piecewise linear approximation, increasing the number of blocks will increase the model accuracy. The number of elasto-slide elements, however, has no bearing on the order of the model, since the blocks are all massless and the springs are in parallel.

Though ostensibly a mechanical formulation, the energy-based constitutive relations of the Maxwell slip model are not domain-specific, and can therefore represent any rate-independent hysteretic relationship between a generalized force and generalized displacement in a lumped parameter causal form. Consequently, in addition to force and displacement, the generalized Maxwell model can represent rate-independent hysteresis between voltage and charge, temperature and entropy, and magnetomotive force and magnetic flux.

The PZT stack actuator model resulting from the aforementioned observations is shown in schematic form in Fig. 9. The generalized Maxwell resistive capacitance, which is represented by the MRC element, resides in the electrical domain and therefore relates the element’s electrical voltage to charge. The PZT model has two ports of interaction, a voltage-current port on the electrical side and a force-velocity port on the mechanical side. With respect to the mechanical side of the transformer, since the actuator model is concerned only with endpoint displacement in a frequency band within the first mechanical mode of vibration, the piezoelectric stack is assumed to have a lumped mass and a linear material stiffness and damping. The behavior of the actuator is therefore described by:

\[
q = Tx + Cv
\]

(11)

\[
v_r = v_c + v_e
\]

\]

(17)

Simulation and Experiment

The model was parameterized for a commercially available piezoelectric stack actuator (NEC model #AE0505D16). This actuator operates at input voltages between zero and 150 volts (in the direction of wafer polarization), which corresponds to an endpoint displacement range of approximately 20 microns. Upon measuring the mass \( m \) of the PZT, the mechanical stiffness \( k \) and damping \( b \) can be determined by observation of the charge-displacement dynamics that are shown in Fig. 3. Measurement of the open-lead stiffness and knowledge of the DC gain between charge and displacement are sufficient to determine the linear electrical capacitance \( C \) and the transformer ratio \( T \).
Equation (8) is replaced with the inverse of a capacitance and each breakaway force of Equation (10) is replaced with an analogous saturation voltage:

$$\frac{1}{C_i} = k_i$$  \hspace{1cm} (18)

$$v_i = f_i$$  \hspace{1cm} (19)

The parameters defining the Maxwell capacitor for the simulations presented herein are given in Table 2. As indicated by the table, these simulations were run with ten elasto-slide elements in the generalized Maxwell resistive capacitor. As previously stated, the Maxwell model is essentially a piecewise linear approximation of rate-independent hysteresis where the number of elasto-slide elements corresponds to the number of linear segments. Increasing the number of blocks therefore increases the model accuracy. The number of blocks required to accurately model a given hysteresis thus depends on the curvature of the hysteresis and the required degree of model accuracy. A real-time application may be better served by fewer elements; since the number of elements does not affect the order of the model, however, the increased computational overhead from added elements is minimal.

Fig. 10 shows the measured and simulated endpoint displacement response of the modeled actuator to a 30, 60, and 90 volt 100 Hz triangle-wave voltage input in the absence of an external mechanical load. As indicated by the plots, the model faithfully represents the voltage input to endpoint displacement output behavior of the PZT actuator. Note in the plots that the displacement output evinces distortion on both the rising and falling slopes and maintains an amplitude-dependent offset. Further observation indicates that this is not typical dynamic distortion. There is no discernible phase lag between the input and output, as indicated by the relative positions of the waveform peaks, and there are no significant filtering effects, evidenced by the fact that the peaks are neither rounded nor otherwise distorted. These observations indicate the existence of a rate-

* The stiffnesses and breakaway forces correspond with the mechanical schematic of Fig. 6.

Independent hysteresis. This hysteric behavior is clearly displayed in Fig. 11, which shows both the measured and simulated data of Fig. 10 plotted as voltage input versus displacement output. Any dynamic system will exhibit an ellipsoid-shaped input-output hysteresis, provided the input is of sufficient frequency to create discernible phase lag in the output. This type of dynamic hysteresis, characterized by a smooth curve relating the output to input, is a result of phase lag between the input and output (such as that shown in Fig. 3). The rate-independent hysteresis of Fig. 10, however, is distinguished from a dynamic hysteresis by the distinct discontinuities exhibited at both extremes. Model accuracy is additionally demonstrated by the data of Fig. 12, which shows the measured and simulated response of the actuator to a linearly decaying 100-Hertz sinusoidal voltage input.

Fig. 13 shows the simulated displacement response to a 10 Hz sinusoidal external force for cases with the electrical leads open and shorted. The simulated behavior accurately reflects the quasistatic measured behavior illustrated by Fig. 4. In addition to providing a structure for numerical simulation, the lumped-parameter model also provides insight into how the electrical properties of the PZT reflect into the mechanical domain. As shown by the measured and simulated data of Figs. 4 and 13, respectively, the PZT actuator exhibits significantly greater stiffness when the leads are open than when the leads are shorted. This change in stiffness can be demonstrated by observing that both the linear and the Maxwell capacitors in the electrical domain reflect as stiffnesses in the mechanical domain. This is similar to the electrical resistance of a DC motor appearing as mechanical damping when the motor leads are shorted. Linearizing the Maxwell capacitor and deriving expressions for mechanical stiffness in both the open and shorted-lead configurations yields

\[ k_e = k + \frac{\tau^2}{C} \] 

(20)

---

**Fig. 11.** Measured (solid line) and simulated (dashed line) voltage versus displacement for a 90 volt 100 Hz triangle-wave voltage input. The difference between the measured and simulated data is difficult to discern.
Fig. 12. Measured and simulated PZT behavior showing voltage and endpoint displacement for a 100 Hz linearly decaying sinusoidal voltage input.
Simulated Force/Displacement Behavior

Fig. 13. Simulated PZT behavior showing force versus endpoint displacement for a 10 Hz sinusoidal external force input for cases with the electrical leads open (dashed line) and shorted (solid line).

\[ L_1 = \frac{m}{T^2} \]  \hfill (23)

\[ R_1 = \frac{b}{T^2} \]  \hfill (24)

\[ C_1 = \frac{T^2}{k} \]  \hfill (25)

This would indicate that driving a typical mass-spring-damper external load would effectively increase \( L_1 \) and \( R_1 \), decrease \( C_1 \), and leave \( C_0 \) unaffected.

Implications for Actuator Control

Several analogies can be drawn between control of a DC permanent magnet motor and control of a PZT stack actuator. First, controlling charge into a PZT actuator is in many ways analogous to controlling current into a DC motor. The relationship between input current and output displacement of a DC motor can be characterized by linear second-order dynamics (one pole serving as a pure integrator). In a similar manner, the relationship between input charge and output displacement of a PZT stack can also be characterized by linear second-order dynamics. Second, just as the output shaft torque is directly proportional to input current in a DC motor when the shaft is locked, the output force of a PZT stack is similarly proportional to input charge when the stack is locked. Continuing this analogy, controlling a DC motor with voltage as input introduces the first-order dynamics of the stator coil inductance and resistance into the system. In a similar manner, controlling a PZT stack with voltage as input introduces the first-order dynamics of the Maxwell resistive capacitor into the system, which unlike the inductor/resistor dynamics of the DC motor, are nonlinear.

Summary and Conclusions

The model presented accurately represents the behavior of a piezoelectric stack actuator in a lumped-parameter real-time rep-
representation, and can therefore be utilized for purposes of model-based control analysis and design. The static hysteresis evinced by the PZT actuator was identified as energy storage coupled to rate-independent dissipation, and was faithfully represented by a generalized elasto-slip model. Despite the presence of this nonlinearity, the relationship between charge delivered to the PZT and endpoint displacement of the stack was observed to have simple second-order linear characteristics. Design and analysis of closed-loop actuator control can therefore be achieved either by incorporating nonlinear techniques with actuator voltage as command, or by utilizing linear techniques with actuator charge as command.
